3

4

5

8

The present work aimed to evaluate the agronomic characteristics correlation of sunflower genotypes grown in seven years in the State of Mato Grosso, Brazil, as an aid for the indirect selection of genotypes. The data were obtained from experiments conducted in the period from 2009 to 2017, in the count of Campo Verde, Mato Grosso, Brazil, using different sunflower genotypes. Pearson correlation analysis was performed among the agronomic characteristics: initial flowering (IF), physiological maturation (PM), plant height (PH), weight of a thousand achenes (WTA), achenes yield (AY), oil content (OC) and oil yield (OY). Strong positive correlation (r =  $0.75^*$ ) was observed between IF and AY and moderately strong positive correlation (r =  $0.67^*$ ) between PM e AY. There was a negative correlation (r =  $0.32^*$ ) and oil (r =  $-0.34^*$ ). Late-genotypes show a positive correlation with achenes yield and oil yield. Smaller plants favor productive parameters. Further studies and anticipation of second crop sowing season are suggested due to local edaphoclimatic conditions.

Keywords: achenes; Central-West; Cerrado; Helianthus annuus L.; oil content.

#### 1. INTRODUCTION

14 15

The area of sunflower cultivation in Brazil has been expanded mainly by the versatility of
 using the crop, as edible oil, for biodiesel production, ornamentation, animal feeding, among
 others [1].

In addition to the varied utilities, the sunflower presents desirable agronomic characteristics, such as short cycle, high quality and quantity of oil, adaptation to different edaphoclimatic conditions, well defined cultural treatments, and is a good alternative for crop rotation/succession [2, 3].

Thus, the crop represents an important income option for Brazilian producers, because in addition to allowing grain production in the off-season, it reduces idleness and optimizes the use of industries, land, machinery and labor [4, 2].

Due to the diversity of use, the desirable cultivation characteristics and the increasing demand of the industrial and commercial sector, there are prospects for an increase in the cultivated area of the sunflower, especially in the Brazilian Cerrado. In this region, it is common to perform a second crop in February/March, in which sunflower cultivation can be used in different production systems [5].

- 33
- 34 In this scenario stands out Mato Grosso, Brazil's largest sunflower producer, which reached

35 98.8 thousand tons in the 2017/2018 crop [6]. In order to maximize production in the state, 36 the importance of the use of adapted genotypes is one of the main factors for the success of

**Comment [U2]:** Reframe the sentence

**Comment [U1]:** Modify the keywords

the establishment of the crop, in order to facilitate cultural practices, reducing the risk of
 losses and providing greater profitability to the producer [5, 7].

In this sense, the agronomic characteristics desirable for the selection of genotypes for a region must meet market demand, especially in relation to the production of achenes, oil content and quality [8]. It is known that the production characteristics of sunflower can be related to each other [5, 9]. The generation of this information is relevant because it allows identifying how plant development characteristics such as height, cycle and weight of achenes can influence final production components.

52

47 The present work aimed to evaluate the agronomic characteristics correlation of sunflower 48 genotypes grown in seven years in the State of Mato Grosso, Brazil, as an aid for the 49 indirect selection of genotypes. 50

#### 51 2. MATERIAL AND METHODS

The data used were obtained from experiments conducted through the Official Evaluation Network of Sunflower Genotypes, under the coordination of the Brazilian Agricultural Research Corporation (Embrapa) Soybean and collaborators. These results were published in the Reports of the Evaluation of Sunflower Genotypes [10, 11, 12, 13, 14, 15, 16].

58 The experiments of 2009, 2010 and 2011 were conducted at Santa Luzia Farm, in the 59 municipality of Campo Verde, Mato Grosso, Brazil. In the years 2013, 2014 and 2016, the 60 tests were carried out in the experimental area of the Federal Institute of Mato Grosso 61 (Instituto Federal de Mato Grosso - IFMT), São Vicente Campus, located in the municipality of Campo Verde, Mato Grosso. And in 2017, in the experimental area of the Reference 62 Center of Campo Verde, also belonging to the IFMT, São Vicente Campus. The experiments 63 64 of 2012 and 2015 were not considered in the joint analysis because the coefficient of 65 variation was higher than 20%.

66

The experimental design was a randomized complete block design with four replications. The sowing was done manually, placing three seeds per hole, and the thinning of the plants occurs between 7 and 10 days after emergence (DAE). In all experiments, the plots consisted of 4 lines of 6 m in length, the spaces used being 0.9 m between rows and 0.25 m between plants, from 2009 to 2014, and 0.7 m between rows and 0.3 m between plants in 2016 and 2017. In addition, the plot area was composed of 9.0 m<sup>2</sup> in the tests from 2009 to 2013, and by 7.2 m<sup>2</sup>, 6.3 m<sup>2</sup> and 5.0 m<sup>2</sup> in 2014, 2016 and 2017, respectively.

In the 2009 trial 18 genotypes were evaluated (Table 1). Seeds were sown on 09 March and were used for fertilizing the 30-80-80 kg ha<sup>-1</sup> NPK and 2.0 kg ha<sup>-1</sup> of boron. 30 kg ha<sup>-1</sup> of N (urea) was applied and the harvest was done between June 24 and July 9. In 2010, 17 genotypes were evaluated. In this experiment the sowing was done on March 10, applying 30 kg ha<sup>-1</sup> of N, 80 kg ha<sup>-1</sup> of P<sub>2</sub>O<sub>5</sub>, 80 kg ha<sup>-1</sup> of K<sub>2</sub>O, 2.0 kg ha<sup>-1</sup> of boron and, in coverage, 30 kg ha<sup>-1</sup> of N. The harvest occurred from July 14 to 21. In 2011, 10 genotypes were evaluated, and sowing was performed on March 4. 30-80-80 kg ha<sup>-1</sup> of NPK and 2.0 kg ha<sup>-1</sup> of boron were used for fertilization in the row and 30 kg ha<sup>-1</sup> of N for cover fertilization. The harvest was carried out between June 17 and 29.

84

In 2013, 16 genotypes were evaluated (Table 2). Sowing was done on March 15 and fertilization using 60-80-80 kg ha<sup>-1</sup> of NPK (04-14-08) and 2.0 kg ha<sup>-1</sup> of boron. In the cover, 30 kg ha<sup>-1</sup> of N (urea) and 40 kg ha<sup>-1</sup> of K (potassium chloride) were applied. The harvest took place from June 15 to July 5. In the year 2014, 16 genotypes were evaluated, of which 5 were excluded due to lack of data for the present study. Sowing was carried out on March

08, with sowing fertilization performed with 500 kg ha<sup>-1</sup> of NPK (04-14-08) and 2.0 kg ha<sup>-1</sup> of 90 boron. At 30 DAE, 60 kg ha<sup>-1</sup> of N and 2.0 kg ha<sup>-1</sup> of boron were applied and the harvest was 91 performed on June 22. In 2016, six genotypes were evaluated whose sowing occurred on 92 93 February 26. For fertilization of sowing, 571 kg ha<sup>-1</sup> of NPK (04-14-08) and 2.0 kg ha<sup>-1</sup> of boron were applied using 82 kg ha<sup>-1</sup> of potassium chloride. The harvest was carried out from 94 95 02 to 16 June. In 2017, five genotypes were evaluated. Seeds were sown on March 16 with fertilization using 30 kg ha<sup>-1</sup> of N, 80 kg ha<sup>-1</sup> of  $P_2O_5$ , 40 kg ha<sup>-1</sup> of KCl and 2.0 kg ha<sup>-1</sup> of boron. For cover, 30 kg ha<sup>-1</sup> of N and 40 kg ha<sup>-1</sup> of K<sub>2</sub>O were used. The harvest was carried 96 97 98 out from June 23 to July 10.

99

In all experiments, at the time of flowering, the plant height (PH) was measured, from the insertion of the stem to the crown region (at soil level). To avoid damage by bird attack, in chapters R7 the chapters were covered with non-woven fabric bags. In the trials of 2014, 2016 and 2017 the initial flowering time (IF) was recorded in days, and in the years 2013 and 2014, the physiological maturation (PM) was also checked in days.

Harvesting and threshing were performed manually with subsequent cleaning of the grain mass to remove the impurities. Then, the weight of a thousand achenes (WTA) was determined, except for the 2014 test, and the achenes yield (AY). Samples containing approximately 200 g were sent for analysis of the oil content (OC) of the achenes. Thus, the oil yield (OY) was calculated by multiplying the yield of achenes by the oil content.

The data were analyzed using statistical software SAS Studio, for analysis of Pearson's correlation among the agronomic characteristics of the sunflower, considering the level of significance of 5%. The results were interpreted according to Shikamura [17] that proposes values of r = 0.10 to 0.19 for very weak correlation; r = 0.20 to 0.39 for weak correlation; r =0.40 to 0.69 indicating moderate correlation; r = 0.70 to 0.89 for strong correlation; and r =0.90 to 1.00 determining very strong correlation.

IF: initial flowering, PM: physiological maturation, PH: plant height, WTA: weight of a thousand achenes, AY: achenes yield, OC: oil content, OY: oil yield; \* significant to 5%.

According to Massignam and Angelocci [18] the initial flowering on the sunflower is more
 related to the genotype, than to the environmental conditions. According to a study by
 Amorim et al. [19], it was found that the flowering contributed considerably with the genetic
 divergences among several sunflower genotypes.

154 One of the objectives of the genetical enhancement has been the selection of earlier 155 sunflower genotypes, as it facilitates the adaptation of the sowing season within the 156 production system, since much of the crop in Brazil is carried out in the second crop. In 157 addition, precocity in flowering, by favoring the anticipation of the harvest, avoids losses from 158 intense rainfall, bird attack or end-of-cycle pests [5, 20].

In spite of these advantages, it is emphasized that the anticipation of flowering and physiological maturation performed in early genotypes should allow final yield similar to those of the medium or late cycle, so that there is no economic loss to the producer. However, the results of the work involving the influence of the anticipation of flowering on the final yield of the crop are contradictory. In a study with sunflower genotypes in Pakistan, Tahir et al. [21] found a positive correlation for the characteristics. On the other hand, Kaya et al. [22, 23] found negative correlation.

In the conditions of the present study, strong correlations (r = 0.75\*) between IF and AY and moderate positive (r = 0.67\*) were observed between PM and AY (Table 3), which allows us to infer that genotypes with cycle later yielded higher yields of achenes when compared to plants whose cycle was earlier. This is possibly related to the fact that later-cycle genotypes present a longer time to produce achenes, tending to higher yields [8].

174 Moreover, according to Santos et al. [24] can anticipate the flowering of the sunflower due to 175 irregularity in rainfall distribution, a common situation in the second harvest crop in the 176 Brazilian Cerrado. Thus, under unfavorable conditions in the phases of flowering and 177 maturation of the sunflower, such as water deficit and high temperatures, there is damage to 178 the accumulation of dry mass by the plants, which causes a negative impact on crop 179 productivity [25]. This may have contributed to the positive correlations observed between IF 180 and AY, and PM and AY, in the present study (Table 3).

182 On the other hand, there was a strong negative correlation ( $r = -0.73^*$ ) between IF and OY 183 (Table 3). Although it was not significant, it was also found a negative correlation between IF 184 and OC (r = -0.19), a relevant result considering that the oil yield is obtained from the 185 multiplication of the achenes yield by the oil content. Similarly, Arshad et al. [26] studying 20 186 sunflower hybrids found negative correlation (r = -0.66) for IF and OC.

187

181

173

188 However, physiological maturation correlated positively ( $r = 0.67^*$ ) with oil yield (Table 3). 189 Considering that the efforts of sunflower breeding programs have been in the development of earlier genotypes with higher production of achenes and oil [8, 27], it is assumed, with the
 results obtained in the present study, that the sowing period adopted and the edaphoclimatic
 conditions of the region were unfavorable for the expression of the productive potential of the
 earlier materials.

In addition to the reduction of the cycle, among the current objectives of the sunflower
breeding programs in Brazil is the smaller size of the plant, aiming at better adaptation to the
climatic conditions at the time of cultivation used and optimization of the harvest practice [8,
27].

199

194

200 In this sense, the negative correlations (Table 3) between PH and IF ( $r = -0.54^*$ ) and PH and 201 PM ( $r = -0.67^*$ ) indicate that there can have been growth restriction of longer cycle plants , 202 especially in the stem elongation period, due to unfavorable edaphoclimatic conditions [28], 203 recurrent in the second harvest in the region of study. Thus, the plants whose initial flowering 204 and physiological maturation were later presented a smaller size at flowering and at the time 205 of maturation.

207 However, the negative correlations observed between plant height and the yield parameters of achenes  $(r = -0.32^*)$  and oil  $(r = -0.34^*)$  for the crop (Table 3) allow to infer that the 208 reduction in the size of the later cycle plants did not affect the final production. Larger plants 209 210 have a higher proportion of leaves, and therefore, they perform carbon fixation more 211 efficiently, which can result in greater accumulation of dry mass in the plant [21]. This greater accumulation of dry mass, because it generates an intense contribution of nutrients to the 212 aerial part in favor of the growth of the plant, can reduce the allocation of nutrients to the 213 214 achenes, resulting in less developed achenes, being able to reflect in a lower yield. 215

For the WTA and OC characteristics (Table 3), a moderate negative correlation was observed (r = -0.51\*), a result similar to those obtained by Mijic et al. [29] and Hladni et al. [30]. According to Leite et al. [8], the achenes located at the periphery of the chapter are heavier in relation to the central ones, and have a larger volume and shell surface in relation to the seed, reason why heavier achenes can have a lower oil content.

222 Although no significant correlation was found between WTA and AY in this study (Table 3), 223 many studies found a positive relationship between these characteristics [9, 19, 22, 29, 31, 224 32]. In sunflower plants, the achenes can be malformed in the center of the chapter, among 225 other factors, by the ripening pattern from the periphery to the center. Thus, depending on 226 the nutritional conditions at this stage, losses in water absorption and photo-assimilates can 227 occur, generating a large amount of achenes achy and floral remains, which can result in lower yield. The influence of the WTA on yield for the crop can also be related to the genetic 228 229 characteristics and the time of filling of the achenes. 230

231 Very strong positive correlation (r = 0.97\*) was observed for AY and OY (Table 3). Corroborating with the results obtained, Dalchiavon et al. [5], Pivetta et al. [9] and Mijic et al. 232 233 [29] found a positive correlation between the characteristics. However, Dalchiavon et al. [5] elucidated that for this correlation, the increase in oil yield of the genotypes should not be 234 attributed to the higher oil content, since the correlations of OC with AY and OY were not 235 236 significant (Table 3). Thus, genotypes that generated higher oil yield were not necessarily 237 the ones with the highest oil content. This same explanation fits the correlation between PH 238 and OY (r = -0.34).

239

With the results obtained, it is necessary to carry out more studies in the evaluated region,
 since the reduction in the plant cycle is a trend in the Brazilian sunflower breeding programs.
 Therefore, it is important to verify if the use of early genotypes in the sowing period used in

243 the region, considering the edaphoclimatic conditions, can imply significant losses, 244 especially in the achenes yield, which constitutes one of the main parameters of interest for 245 the crop. 246

#### 4. CONCLUSION 247

In the conditions of the present work, the later cycle genotypes present positive correlation with the production parameters of achenes yield and oil yield.

252 For plant height, negative correlations were observed with the characteristics: initial 253 flowering, physiological maturation, achenes yield and oil yield.

It is necessary to carry out further studies, especially with early genotypes, suggesting the anticipation of the sowing season of the second harvest considering the local edaphoclimatic conditions.
