6 **Abstract**

25 **1. Introduction:**

Drought is one of the natural disasters that human being has been suffering since the ancient era [71, 73,20] and it is the costliest [67,21], long-lasting most severe natural hazard [43,44]. It is recurrent natural phenomena associated with the lack of water resources for a prolonged period of dryness[46,58,64] can occur in arid, semi-arid and rain-forested region [42,1] however confusion and debates among scholars prove that there are no universal accepted definitions of drought. Drought forecasting is a critical element in drought risk management

Comment [P1]: What are you now recommending? Include it here.

Comment [P2]: Capital and small letters mixed.

Comment [P3]: Why should first citation begin with 71 rather than 1? Please correct this. Start from no 1 to the last citation number.

[49]. Meteorological drought that transforms in a hydrological, agricultural and socio-economic events, onsets with a marked reduction in rainfall sufficient to trigger hydro-meteorological imbalance for a prolonged period [68,43,45,24].Thus drought monitoring and assessment are hot topics among hydrologists and meteorologists and attract world-wide attention [33, 58]; its' preparedness and mitigation depends upon the large scale drought monitoring and forecasting over a large geographical area [49,70,71,3,4]. Many drought forecasting models already develop in the field of civil engineering. Mishra and Desai (2006) [41] developed ARIMA and multiplicative seasonal ARIMA models to forecast drought using SPI series. These models are able to simulate drought up to 2 months lead time. Morid et.al 2007 [45] simulated Effective Drought Index (EDI) and SPI using Artificial Neural Network (ANN). Mishra and Desai (2007) [42] compared linear stochastic models with recursive multistep neural network model to the 6 months lead time. Barros and Bowden (2008) [9] employed self-organizing maps (SOM) and multivariate linear regression analysis to forecast SPI of Murray Darling basin of Australia in 12 months of forthcoming scenarios. Many scholars worldwide tested SVM in climatological and hydrological applications [16, 6, 59, 65, 66]. There are several scholars used SVM to predict drought [16,19,59,65] . Belayneh and Adamowski in 2012 [11] forecasted meteorological drought using neural network, wavelet neural network and SVM. Exponential smoothing is quite new in this field originally developed in the field of business mathematics in 1960. Exponential smoothing is able to simulate drought in a long term time frame. This study attempts to simulate drought using exponential smoothing in a long-term time frame.

2. Study Area and Background Information

54 The District Bankura is bounded by $22^038'$ N to $23^038'$ N and longitude $86^036'$ E to $87^047'E$ covering an area of 6,882 square Kilometers (2,657sq. mile). River Damodar creates the north and north-east boundary of the district [18]. The neighboring districts are Bardhaman in the north, Paschim Medinapore in the south, Hoogly in the east and Purulia in the west (Figure 1). Bankura is a historically a drought prone district and if no supportive action taken quickly in this regard the condition will get much severe in the upcoming periods [13,36, 51,52].

-
-
-
-

Figure 1 Bankura Location Map and location of Meteorological Stations

Bankura is located in the south western central part of the State of West Bengal belonging transition zone between the plains of Bengal on the east and Chhota Nagpur plateau on the West [13,18]. It is a part of Midnapur Division of the State and a part of "Rarh" region thus can be stated as "Rarh in Bengal' [47]. The areas to the east and north-east are rather flat belonging to the low lying alluvial plains, known as rice bowl of Bengal [18, 17, 48].

3. Data Sets and Methodology

Figure 2 constructively describes the methodological overview of this paper. Monthly rainfall data 1901-2017 has been used for overall analysis and 1901 to 1978 data obtained from Govt. of India water portal website mentioned in Table 1. From 1979 to 2014 daily station wise rainfall data obtained from National Centres for Environmental Protection (NCEP) official website. The rainfall data were collected from Disaster Management Plan of Bankura District 2017 published by District Disaster Management Cell (Table 1) and got 6 individual rainfall stations available for Bankura District and monthly and daily rainfall data have been added to get yearly rainfall trend. Thus 117 years are taken into consideration.

Comment [P4]: Is it not Material and Method?

92 **Table 1** Source of Rainfall Data

B

96 **3.1 Formation of Standardized Total Drought (Sd)**

There are several indices developed to assess meteorological drought but the most common are SPI [23, 40], DI [27], PN [28], Z-Score [20], RAI [25,44,53] and CZI [14]. First of all, from the rainfall data, the above mentioned 6 well-known indices i.e. SPI, DI, CZI, PN, Z-score, and RAI have been estimated on yearly basis and later those are combined and formed 101 a new Index Standardized Total Drought (S_d) . So, those six indices are utilized to estimate the true nature of meteorological drought and standardized total drought (yearly basis) becomes the sole input variable for every models of our study.

104 It can be computed as follows:

105 Total Drought $(T_d) = (SPI + DI + PN + ZScore + RAI + CZI)$ (1)

- Standardized Total Drought(S_d) = $\frac{T_d \overline{T_d}}{\delta}$ 106 Standardized Total Drought(S_d) = $\frac{1 \text{ d}-1 \text{ d}}{\delta}$ (2)
- 107 Where, T_d is the total drought.
- 108 $\overline{T_d}$ is the mean of T_d
- 109 δ is the standard deviation of the total drought.

110 Based on estimated S_d values the individual drought categories are subdivided into 9 sub-groups. he whole subgroups are ranging between <-10 to >10 category and <-10 denotes the most extreme category whereas >10 denotes wet category. Every 9 sub categories are coded as 1 to 9 (table 2).

114 **Table 3 Probable classes of Standardized Total Drought (Sd)**

Categories of Drought	Code	Ranges of Drought
Most Extreme		$<$ -10.00
Extreme	\overline{c}	-3.00 to -10.00
Severe	3	-2.99 to -2.50
Severe Moderate	4	-2.49 to -2.35
Moderate	5	-2.35 to -1.15
mild drought	6	-1.15 to 1
Normal	7	$1-5$
Extreme Normal	8	$5-10$
Wet	9	>10

3.2 Exponential and Holt-Winter Forecast and Winexpo Method: Exponential smoothing is the technique to smoothing the time series in exponential window function. Exponential smoothing assigns decreasing weights over time. Holt in 1957 and Winter in 1960 developed smoothing technique and later their method was combined and making Holt-Winter smoothing technique to forecast the recursive trend from the historically observed data series [12,26,30]. Here we use the single exponential smoothing technique as Kaleker in 2004 [34] used in his thesis: $S_{t+1} = \alpha * y_t + (1 - \alpha) * S_t$ $0 < \alpha < 1, t > 0$ (3) Eq. (11) can be written as $S_{t+1} - S_t = \alpha * \varepsilon_t$ (4) The Holt-Winter method time series can be represented using the following model: $y_t = (b_1 + b_2 t) * S_t + \epsilon_t$ (5) 128 Where b_1 is the permanent component, b_2 is the linear trend component, S_t is the 129 multiplicative seasonal factor, ϵ_t is the random error component, t is the time and t+1 is the lead time from t. From the Eq. (13) $S_t = \frac{y_t}{b_1 + b_2}$ $S_t = \frac{y_t}{b_1 + b_2 t} + \epsilon_t$ (6) Sum of all the seasons can be written as $\Sigma_{t=12} S_t = M$ (7) 135 Where L is the length of the year. So, the Eq. (7) can be written as, $\sum_{t=1}^{12} y_t = (b_1 + b_2 \sum_{t=1}^{12} t) * \sum_{t=1}^{12} S_t + \epsilon_t$ (8) 138 Assuming, $\sum_{t=1}^{12} y_t = Y$, $\sum_{t=1}^{12} t = T$ and $\sum_{t=1}^{12} S_t = M$ we get from Eq. (16) $Y_t = (b_1 + b_2) * M + \varepsilon_t$ (9) And Eq. (14) can be written after the sum of all the seasons $M = \frac{Y_t - \varepsilon_t}{b_1 + b_2 T}$ (10)

6

Comment [P6]: Remove

Winexpo method has been developed by us to combine the traditional exponential and Holt-Winter method. Combining Eq. (12) and Eq. (18) we get,

144
$$
\frac{S_{t+1} - S_t}{M} = \frac{\alpha * \varepsilon_t}{\frac{Y_t - \varepsilon_t}{b_1 + b_2 T}}
$$
(11)

145 Or,
$$
\frac{S_{t+1}-S_t}{M} = \frac{\alpha*(b_1+b_2T)}{(Y_t-\varepsilon_t)} + \varepsilon_t
$$
 (12)

Winexpo is one of the integrative models as it holds the combination of Holt-Winter exponential smoothing and traditional exponential smoothing.

3.4 Support Vector Machine model (SVM)

Support Vector Machine (SVM) is the supervised learning models that analyse data used for classification and regression analysis [7,15,61,62,63]. The x related all points can be mapped 151 in the hyperplane can be defined by the relation $\sum_i \alpha_i k(x_i, \bar{x}) = constant$ where k (x_i, \bar{x}) is the kernel function used to suit the problem. Kernel function becomes small where y grows further away from x so it becomes the matter of closeness of each point of y to x. With the kernel function SVM actually use the relative closeness between the each point in the feature space. The detailed method of analysis can be expressed as following:

156 Suppose our training data is consist of N pairs (X_1, Y_1) , (X_2, Y_2) ………….. (Xn, Yn); where 157 Xi $\in \mathbb{R}^p$ and $Y_i \in \{-1, 1\}$. Define a hyperplane by, $\{x: f(x) = x^T\beta + \beta_0 = 0\}$, where β is a unit 158 vector. A classification rule induced by $f(x)$ is $G(x) = sign \{x^{T}\beta + \beta_0\}$. Now the signed distance from the point x to the hyperplane is 0. Here we are able to find the hyperplane that creates biggest margin between training points for class 1 and -1. So, the optimization problem just reverses and forms the following dimension:

162
$$
\max_{\beta, \beta_{0, ||\beta||} = 1} = M
$$
 (13)

Subject to,

164 subject to,
$$
y_i\{x^T\beta + \beta_0\} \ge M
$$
; i = 1,2,, N (14)

We have used here Least Square Support Vector Machine is based on structural risk minimisation [61,62] in the model weight. It counters convex quadratic programming associated with Support Vector Machine (SVM) [56, 57]. The least square version of the SVM classifier is obtained by reformulating the minimization problem as

169
$$
\min J_2(w, b, e) = \frac{\mu}{2} x^T \beta + \frac{\infty}{2} \sum_{i=1}^N e_i^2
$$

170 Subject to equality constraints,

171
$$
y_i[x^T\beta + \beta_0] = 1 - e_i, i = 1, 2, \dots, n
$$
 (15)

- 172 Eq. 36 can be written as
- 173 $e_i = 1 y_i [x^T \beta + \beta_0]$ (16)

174 The eq. 37 hold the case of regression. To solve the eq. 37 we use Lagrangian multiplier by 175 which it can be solved.

176
$$
L_2(w, \beta, e, \alpha) = J_2(w, e) - \sum_{i=1}^n \alpha_i \{ [\beta + \beta_0] + e_i - y_i \}
$$
 (17)

177 Where, $\alpha_i \in R$, the Lagrangian multipliers. For evaluation performance test of SVM we use 178 the error estimation and Kappa Coefficient statistic as well as the accuracy. The definition of 179 Cohen's Kappa is as follows [26, 54]:

180
$$
k = \frac{p_0 - p_e}{1 - p_e}
$$
 (18)

181 Where, P_0 is the relative observed agreement among variables; Pe is the hypothetical 182 probability of chance agreement. If the rates are in the complete agreement then $k = 1$ and if 183 there is no agreement then $k = 0$.

184 **3.7 Estimation of Cumulative Hazard Proneness:**

To estimate the cumulative drought-proneness of the study region over the years we took help of the hazard function and survival analysis[7]. Let T be a non-negative random variable representing the waiting time until the occurrence of an event. For simplicity we can adopt the term 'survival analysis' referring to the event of interest as 'hazard proneness' and to the waiting time we state as 'survival time'. We can assume T is a continuous random variable with probability density function (p.d.f.) f(t) and cumulative distribution function (c.d.f.) 191 Pr $\{k < t\}$ given that probability that the event has occurred by duration t. Complement of c.d.f. the survival function becomes

193
$$
S(t) = Pr{T \ge t} = 1 - F(t) = \int_{t}^{\infty} f(x) dx
$$
 (19)

194 Which gives probability of being 'less drought prone' just before duration t more generally 195 the probability that the event of interest has not occurred by duration t. Here we use the

243 and m_1 m_n are the expected values of the order statistics of independent and identically distributed random variables sampled from the standard normal distribution, and V is the covariance matrix of those order statistics.

4. Application and Discussion

247 Fluctuation of rainfall and a negative exponential trend are specified in Figure 3 (Y_t = 248 1418.88 \times (0.999642^t). Rainfalls are more or less normally distributed at 95% confidence interval (Figure 4a). Residuals versus fit plot (Figure 4b) displays that the points are randomly distributed on both sides of zero with no recognisable patterns thus our rainfall data are having a constant variance. Residuals of rainfall are having a mean close to zero and the histogram is symmetric close to around zero (Figure 4c). Residuals versus order fit (Figure 4d) shows that the residuals fall randomly around the centre line. Before proceed with rainfall and estimated 6 indices the reliability of those 6 indices are judged using Cronbach's Alpha. The overall value of Cronbach's alpha is 0.9694. Average SPI and Z-score between the time frame 1901-1939 are -0.06 and 0.299 , in between 1940 -1980, 0.037 and 0.382 respectively and from 1980-2035 the average SPI and Z-score becomes -2.345. Average PN value from 1901-1939 is 100.792 %, 1940-1980 PN becomes 100.641%; 1980-2035 it is diminished and become 98.967%. In the same way average DI is estimated and from 1901-1939 DI 5.76%, 1940 to 1980 5.73% and DI from 1980 to 2035 4.64% value of DI is obtained. CZI and RAI are also decreased from 0.32 (1901-1939) and 0.38 to 0.26 (1940-1980) ,0.28 and later 1980- 2035 it reaches to 0.14 and 0.19. Overall all the indices attain negative trend. SPI, PN, DI, 263 RAI, CZI and Z-score are added and a new index Standardized Total Drought (S_d) has been formed to estimate overall trend of meteorological drought of Bankura District. Estimation 265 and prediction of the trend of S_d using the traditional exponential smoothing has been done and a slightly negative trend is obtained (Values reach to -0.143 in 2035) (Figure 5a). The residuals of traditional exponential smoothing trend values are ranging between -15 to +5 (Figure 5b). In case of traditional exponential smoothing the average value between 1901- 1939 experiences -0.170, 1940 to 1980 the value reaches to -0.034 whereas between the 1980 to 2035 the average value attains -0.134 thus overall trend is seemed to be more drought prone in recent upcoming periods. Similarly using Holt-Winter exponential smoothing analysis and prediction of drought has been done (Figure 5c) and residuals are fitted randomly as histogram plot based on the centre line (ranging between -2 to +5 range) (Figure 5d). In case of Holt-Winter exponential smoothing the average value between 1901-1939 achieve -0.163, between the time frame 1940-1980 and 1980 to 1935 it attain 0.061 and -

Comment [P11]: Result and Discussion?

0.261 values respectively. The combined model Winexpo attains 0.423 for 1901-1939, 0.51 for 1940-1980 and -1.423 for 1980-2035.

303 From the true classes determined from the categories of S_d SVM is capable to predict the nature of drought category. A user friendly SVM tool LSSVM is used to implement the classification of drought status of Bankura District. At data pre-processing stage raw values 306 of S_d are linearly rescaled into [-1, 1] using the ranges of their minimums and maximums for binary distribution of classifiers. Applying the SVM each category against all is estimated in every case. In case of Extreme vs. others the model is obtained 43 support vectors, for extreme normal the model is obtained 33 support vectors, for mild drought the model obtains 34 support vectors, most extreme the model obtains 28 support vectors, normal vs. others obtains 51 support vectors, severe vs. others obtains 8 support vectors and wet vs. others

obtains 20 support vectors. From the observed true classes of 135 observations (used simulated value using Winexpo) drought probability classes are predicted by SVM. SVM performs with a medium accuracy level. According to SVM identified drought categories over years over 80% years are concentrated within severe moderate, severe, extreme and most extreme categories and about 20% years are concentrated within Moderate, Normal, and Extreme Normal, wet categories (Figure 6a) whereas according to Winexpo identified drought categories 36% years are mingled with severe moderate, severe, extreme, most extreme and moderate categories and over 64% are mingled with normal, mild, extreme normal and wet categories (Figure 6b). The extreme normal versus others, wet versus others, mild versus others, normal versus others training sample sets achieve over 90% accuracy whereas extreme and most extreme versus others and severe moderate versus others category training samples achieve less than 30% accuracy (Table 4). Overall average SVM achieve 0.724 as Cohen's Kappa and overall 60% accuracy has been achieved. So, SVM has performed moderately well in prediction of drought of our study area.

Figure 6 Frequency of drought under each drought categories a) based on simulation model of SVM b) based on simulation of Winexpo

340 **Table 4 Performance matrix of Support Vector Machine (SVM)**

341

The significance test using three individual tests has been run at 95% and 99% confidence interval (Table 5). The traditional exponential smoothing experiences probability value 0.004 for Anderson-Darling test, 0.005 for Shapiro-Wilk test and 0.004 by Kolmogorov-Smirnov test. The Holt-Winter exponential smoothing attains 0.003 probabilities for Anderson-Darling test, 0.004 for Shapiro-Wilk test and 0.001 for Kolmogorov-Smirnov test. Winexpo model also attains probability value 0.002 for Anderson-Darling test, 0.004 for Shapiro-Wilk test and 0.003 for Kolmogorov-Smirnov test. The Bayesian model of LSSVM extreme category vs. other categories experiences 10.275 as Anderson-Darling test statistic value, 0.527 as Shapiro-Wilk test statistic value and 0.435 as KS test statistic value. LSSVM Bayesian most extreme vs. other category is mingled with 5.543 as Anderson-Darling test statistic, 0.727 as Shapiro-Wilk test statistic and 0.316 as KS test statistic. SVM extreme normal vs. other categories achieves 2.165 as Anderson-Darling test statistic, 0.904 as Shapiro-Wilk test statistic and 0.482 as KS test statistic value. Similarly, Mild versus others, severe versus others, severe moderate versus others and wet versus others are also calculated (Table 5). All the Anderson–Darling test is successful and valid at 95% confidence interval as the significance level P-value achieves <0.005 value in all the nine combinations. Shapiro-Wilk and KS test for all the SVM nine possible combinations the probability value is <0.010 that means those values are significant at 99% confidence interval. Overall SVM model is significant at 95% confidence interval (in case of Anderson-Darling test) and 99% significance level (in case of Shapiro-Wilk test and KS test). As P values are <0.005 and <0.010 for all the cases the distribution is not normal here and null hypothesis that there were no difference between the observed class and predicted class can be rejected and the alternative hypothesis is accepted. The error estimation and goodness of fit statistics (Table 6) of the individual models indicate that Winexpo attains the lowest error and highest R-square value in comparison with the other models altogether.

367 **Table 5 Error Estimation and Goodness of fit statistics (for error estimation 0.001 used**

368 **as a multiplicative factor)**

â

370 **Table 6** Significance test of the models

Based on Winexpo and SVM model simulation the hazard prone zones have been estimated (Figure 6). The southern and south-western blocks are extreme drought-prone and northern 373 and north-western blocks are mild to normal mode. The whole regimes form the coherent 374 clusters in space highlighted in figure 7. Most extreme to severe drought categories are clubbed into negative x, y direction and wet categories are clubbed into positive directions of x and y. Based on the whole aspects of meteorological drought the year wise hazard and cumulative failure functions are developed. The most extreme, extreme, severe, severe moderate, moderate and mild categories are included in the category of "hazard prone or failure "whereas normal, extreme normal and wet categories are included in "censored" category. Winexpo attains the best result so this model has been used here. According to simulation of drought category using winexpo, almost 84 observations are fallen into "hazard-prone" category and 51 observations have fallen into the "censored" group. The distribution of yearly censored and failure categories are compared based on Weibull and logistic probability fit but logistic probability fit gave us the better association (Correlation value 0.984 for logistic and 0.678 for Weibull). So, finally the logistic probability fit have been taken for year-wise estimation of cumulative hazard-proneness. The whole logistic model seemed to be more or less normal (Figure 8a and 8b) and it had achieved the 3.223 value as the Anderson-Darling test. From the survival function (Figure 8c) fitted based on logistic probability plot encounters the fact that as the time (year) will progress the drought proneness will increase and at the year 2100 the vulnerability will be almost intolerable that will lead to massive disruption over the local community. Reversely, the progression of hazard based on cumulative curve plotting (Figure 9, figure 8d) exhibits the fact that the whole district will be severely affected by drought within 2100. The significance test for hazard function is done in 95% significance level .So, it can be concluded that the district will face extreme to severe drought hazard in the recent future.
