1 2 3

6 Abstract

7 The low temperature is one of the most used techniques to maintain fruit quality over 8 long time storage and consequently the fruit respiratory metabolism is directly 9 influenced. In addition, the combination with another postharvest treatment aiming to 10 maintain the fruit quality and increase the banana shelf life seems to be an 11 alternative to improve banana postharvest attributes. Therefore, the combination of 12 CaCl₂ and hydrothermal treatment can be an important alternative to improve banana 13 fruit quality and influence the ratio starch/sugar and consequently quality traits. 14 Based on the hypothesis, the calcium and hydrothermal works synergistically 15 modulating banana primary metabolism and skin color changes. The starch content 16 and chrome parameters were kept in higher values at 2% and 3% (w/v) of CaCl₂. 17 However, the fruit storage at control condition have shown lower fresh weight loss 18 (%), followed by total soluble solids and sugars content. Our study showed that, fruit 19 firmness, titratable acidity, skin brightness and hue angle were not significantly 20 influenced by the treatments. However, banana fruits when treated only by 21 hydrothermal treatment maintained better postharvest quality trait when compared to 22 the fruits of the hydrothermal treatment associated with calcium chloride. The 23 hydrothermal treatment when combined together with CaCl₂ can have influence on 24 the banana fruit quality affecting skin color and primary metabolism such as sugar 25 and starch content.

26

27 Key-words: Calcium chloride, fruit quality, central metabolism, Postharvest

28

29 **1. INTRODUCTION**

The fruit quality is an important characteristic to be considered during commercialization, mainly when the fruit is directly designated to consumption freshly as in case, banana fruits. Noteworthy, problems associated with the production and

33 high domestic consumption and postharvest diseases, the main restrictive factor for 34 exportation market is the low postharvest management technology of fruits 35 Lichtember and Lichtemberg, 2011). In addition, one of the most widely used 36 techniques used to guarantee increased shelf life in several climacteric fruits is the is 37 the refrigeration system. These effects is mainly due influences on metabolic rates, 38 affecting respiratory process, which in turn delays ripening, leading increases in the 39 shelf life of these fruits De Oliveira et al., (2017). However, bananas fruit when stored 40 at temperatures below 13 °C, there is a classical disorders associated with chilling 41 injury, called chilling, causing the skin browning, affecting the visually quality-trait 42 which leads to lower acceptance by consumers (Nuven et al., 2003). Furthermore, 43 according De Morais et al., (2012), the refrigeration techniques alone is not sufficient 44 to maintain fruit quality for long periods, and it is necessary to use other conservation 45 techniques to improve the performance, such as edible coating (Hernámdez-Munoz 46 et al., 2008), hydrothermal treatment (Salvador-Figueroa et al., 2011), chloride 47 calcium treatment (Hernámdez-Munőz et al., 2008).

48 The hydrothermal treatment used to control pests attacks and diseases 49 incidences in various fruits (Moraes et al., 2006; Ribeiro et al., 2018; Salvador-50 Figueroa et al., 2011). As a consequence, this technique provides an additional 51 advantage to the maintenance of the quality standard of the fruits such as inducing 52 protein specialized in protein repair. Moreover, in our knowledge, the postharvest 53 characterization of banana fruit cv. 'Prata Gorutuba' still remains poorly understood, 54 mainly associating hydrothermal treatment with calcium chloride. The hydrothermal 55 treatment is well known to affect the fruit metabolism and increases thermo-tolerance 56 (Lurie, 1998). Remarkable, enabling storage at a lower temperature than the one 57 normally recommended, thus providing greater fruit conservation (Schirra et al., 58 2004). The calcium ions play a crucial role in plant cell physiology. They are 59 important intracellular massagers and can act as a mediator to hormones. 60 Additionally, calcium plays an essential role in the membranes and cell wall structural 61 maintenance, mainly cross-linking free carboxyl groups on adjacent 62 poligalacturonase chains present in the middle lamella of the plant cell wall 63 contributing to cell-cell adhesion and cohesion (Brummell & Harpster, 2001). 64 Postharvest treatment with calcium salts have been effective in controlling several

65 physiological disorders, reducing the incidence of fungal pathogens and improving

the fruit quality (Barman et al., 2018; Madani et al., 2014; Silva et al., 2015).

67 The association between between hydrothermal treatment and calcium 68 chloride has been investigated in different fruits such as pineapple (Annas comosus) 69 (Youryoun et al., 2018), Atemoya (Annona cherimola Mill × A. squamosa L.) (Rasai 70 et al., 1994), Fig fruit (Ficus carica) (Irfan et al., 2013) and papaya (Ayón-Reyba et al., 2017; Madani et al., 2016 and Madani et al., 2014). Taken together, in our 71 72 understanding, the results are still poorly understood and so far to be completely 73 understood. Therefore, we our research has proved a physiological mechanism 74 involved the low hydrothermal treatment in association with calcium in to 75 maintenance of banana fruit quality and extends shelf life. Once, it is already known 76 that hydrothermal treatment when investigated singly in banana fruit has provided 77 better physical, chemical and phytosanitary quality of fruits (Ribeiro et al., 2018). 78 Considering what was addressed, our research aimed to evaluate the application of 79 calcium chloride after hydrothermal treatment on postharvest quality maintenance of 80 banana fruit cv. 'Prata Gorutuba'.

81

82 2. MATERIAL AND METHODS

83

84 2.1. Fruit material and environmental conditions

85 The fruits were purchased from the commercial plantation located in Mocambinho, 86 Jaíba, Minas Gerais, Brazil. The area is located in the extreme north of the state of 87 Minas Gerais, at 15 ° 12 'south latitude and 43 ° 47' west longitude, with an altitude of 88 483m. The bunches were harvested twenty weeks after the inflorescence emission, 89 at stage 2 (green with yellow dashes) of maturation according to the scale of Von 90 Loesecke (PBMH & PIF, 2006). After harvest, the fruits were packed in plastic boxes 91 lined and covered with papers and transported to the laboratory. The banana fruits 92 were selected according to their visual appearance, discarding damaged fruits as 93 well as fruits with mechanical lesions. After selection, 4 banana fruits per banana 94 bunch were kept, sterilized and washed. The fruits were treated with fungicide 95 Imazalil (Magnate®) according to the manufacturer's recommendations. The 96 statistical experimental design was completely randomized involving two main factors

such as, five different calcium chloride concentration (0, 1, 2, 3 and 4% w/v) during 7
times of treatment.

99

100 2.2. Postharvest treatment

101

102 The hydrothermal treatment was performed in a water bath at 54°C, for 5 min 103 under immersion (time defined in preliminary experiments). The fruits were then 104 cooled in room temperature water (± 25°C) for min 5 min. After this period, the fruits 105 were treated with calcium chloride by immersion for additional 5 min in 106 concentrations of 0 (Control), 1, 2, 3 and 4% CaCl₂ (w/v). The fruits were dried on 107 benches in room temperature and then stored in low density polyethylene packages 108 of 16µm at 13.5 ± 1°C and relative humidity (RH) 85±5 % for a duration of 30 days 109 and samples were collected every 5 days for 35 days (7 time-points).

110

111 2.3. Fruit fresh weight loss (%)

The banana fruit fresh weigh loss was determined as previously described by Hernández-Munõz *et al.*, (2008) and Batista-Silva *et al.*, (2018). The banana fruits were weighted at the beginning of the experiment after coating and air-drying, and thereafter each day during the storage period. The fresh weight loss was expressed as percentage loss of the initial total.

117

118 2.4. Physical quality attributes

119

120 The fruit's skin color analysis was performed using a colorimeter Color Flex 121 45/0(2200), stdzMode:45/0 with direct reflection reflectance of the coordinates L* 122 (brightness) a^* (red or green tonality color range) and b^* (yellow or blue tonality 123 range) according with Hunterlab Universal Software system. From the L*, a* and b* 124 values, were determined the hue angle ($^{\circ}h^{*}$) and the saturation Chrome index (C^{*}). 125 The fruit firmness was performed using a digital texturometer (Brookfield model CT3 126 10 KG) with 4 mm Ø. The evaluation made in two equidistant regions on opposite 127 sides. The firmness was measured as the maximum penetration force expressed in 128 Newton (N).

130 2.5. Determination of chemical quality parameters

131 After physical measurement, in order to understand the effects hydrothermal 132 treatment associated with CaCl₂, we performed the soluble solids concentration 133 (SSC) and titratable acidity (TA), pH, starch and sugars content. For the SSC 134 determination, a handheld refractometer (Model N-3000E, Atago, Japan), calibrated 135 with distilled water prior the readings was used. The titratable acidity (TA) was 136 analyzed according to the method of (Ranganna, 1986). The results of TA were according to malic acid content per 100 g^{-1} of banana pulp. The pH was measured by 137 138 using pH meter Crison MicropH 2001 (Crison Instruments SA, Barcelona, Spain).

139

140 2.6. Physiological parameters

141

The soluble sugars were determined by the anthrone method according Dubois *et al.*, (1956). The quantification of starch was carried out according to the method described by Yemm and Willis (1954). The starch was obtained by spectrophotometry, with reading at 510 nm, according to the method described by Nelson (1944).

147

148 2.7. Pectinmethylesterase activity (PME)

The enzymatic extraction was according with Buescher and Furmanski (1978), with modification as described in details by (Vilas-Boas & Kader, 2006). The PME activity determination according Hultin *et al.*, (1966).

- 152
- 153 2.8. Experimental design and statistical analyses
- 154

The experiment was performed in a completely randomized design (CRD), with four repetitions. Statistical analyzes were performed using the Sisvar software (Ferreira, 2011).

159 3. RESULTS AND DISCUSSION

160

161 2.9. The role of hydrothermal treatment and CaCl₂ in the physical attributes in
162 banana fruits.

163

164 Ripening is a complex process genetically programmed, culminating in 165 dramatic changes, mainly in color and fruit texture (Osório et al., 2013). In order to 166 characterize better the role of hydrothermal treatment and CaCl₂ in the physical 167 attributes in banana fruits we measured some physical attributes. The fresh weight 168 loss (FW) was significantly affected (p < 0.05) by days after storage and also by CaCl₂ 169 concentration. The FW loss increased during fruit ripening over storage time (Fig. 170 1A). The FW loss average at 30 days after storage was around 1.23% independently 171 of treatment concentration. The increase in FW partially explained by respiration and 172 fruit transpiration and seems to be the major determinant of storage life and guality of 173 banana (Hailu et al., 2013). Furthermore, according with Kader (2008), the FW loss 174 range admissible is around 5 and 10%. Our results in the meantime did not reach 175 5%, which did not compromise the final fruit quality at 30 days of storage. As the 176 CaCl₂ concentration increased, the FW loss increased proportionally (Fig. 1B), which 177 presented 0.45% and 0.85% of FW loss to 0 and 4% (w/v) CaCl₂, respectively. 178 Interestingly, control treatment (0%) and 1% showed significantly smaller averaged of 179 FW loss. Similar results was observed in guavas cv. Cortibel by Terra Werner et al., 180 (2009). The effect of the salt present on banana's fruit skin surface can cause 181 dehydration, increasing the FW loss during the fruit storage (Azzolini et al., 2004).

182 According with skin brighthless (L^*) , as an important fruit/vegetable postharvest 183 parameter once is possible to identify the visual appearance. The L * values range 184 from 0 for fully black samples to 100 for totally white samples, the lower values 185 indicate opaque shell (No brighthless) and higher values indicate brighter fruits 186 (Lancaster et al., 1997). Our results have shown significant effects (P<0.05) of 187 storage times under banana's fruit L^* . During fruit ripening, the L^* increased (45.82) 188 at 0 day after treatment to 58.47 at 30 days after treatment storage at 13.5°C (Fig. 189 2A), which are indicating increases in fruit brighthness over fruit ripening which are 190 significantly correlated to skin pigments (Chlorophyll and Carotenoids) changes 191 (Song et al., 1997) which can be influenced by ethylene (Kajuna et al., 1998). Our

192 results is in agreement with previously observed results by Castricini et al., (2015). 193 As to L^* , h^* was significantly affected by fruit ripening without changes by treatment 194 (Fig. 2B). However, no effect was observed by hydrothermal treatment and neither by 195 calcium concentration. As expected, h^* decreased during fruit ripening and remained 196 within the angular range of the green color until around the 15th day of storage with 197 93.76°, which shows that there was delay in the ripening process. The changes of 198 coloration occurring during the ripening of the fruits are related to the degradation 199 and / or biosynthesis of pigments (Gross, 2012). In the banana, chlorophyll 200 degradation (green color) is intense during maturation, showing the pre-existence of 201 carotenoid pigments (yellow to orange color), while the synthesis of other pigments is 202 performed at relatively low levels (Silva et al., 2006). Chromaticity is an objective 203 specification of the quality of a color regardless of its luminance (Hunt, 1977). 204 Chroma values around (0) zero represent neutral colors, while values close to 60 205 express intense colors and it means ripe fruits (Mendonca et al., 2003). Chroma 206 values slightly increased during storage period and was also significantly influenced 207 by CaCl₂ treatments (Fig.3). Although a linear increase of Chroma was observed 208 during fruit ripening over storage time, fruits treated with 2 and 3% of CaCl₂ had a lower color intensity of the skin color with average of Chroma of 37.96 and 37.75, 209 210 respectively (Figure 3B).

211 The fruit firmness as expected was influenced significantly (P<0.05) by fruit 212 ripening over storage period (Fig. 4). However, the CaCl₂ treatment, independently of 213 the concentration has not influenced the fruit firmness. Our results has shown a 214 oscillation in the fruit firmness values with 36.03 N at 5 days after storage period and increased up to 50N (15th days after storage), followed by a drastic reduction at 30 215 days after storage (29.23 N) (Fig.4). In our understanding, this variation may be 216 217 explained due to unevenness in banana's fruit ripening. The firmness loss in fruits is 218 generally associated with the action of pectinolytic enzymes, which leads to 219 destabilization of the cell wall. According with (Santos et al., 2018), mean values of 220 firmness can be found in banana cv. 'Prata-Anã' ranged from 32.8 N ~ 40 N at 25 221 days of refrigerated storage under 13.5 °C. The fruit firmness is generally associated 222 with the integrity of the cell wall, the middle lamella and the cellular turgor, which both 223 are directly dependent of water potential (Brummell, 2006 and Brummell et al., 2001). 224 Therefore, losses in mass due to dehydration and respiration, very common during

storage, decreases turgidity, affecting fruit firmness. According to Brummell (2006),
the loss of firmness of the fruit is an unavoidable characteristic in the ripening
process, which is caused by the progressive cell wall solubilization.

228

229 2.10. The role of hydrothermal treatment and CaCl₂ in the chemical attributes in 230 banana fruits.

231

The SSC were significantly (P<0.05) affected by ripening process as well as to 232 233 CaCl₂ treatment associated with hydrothermal pretreatment (Fig.5). The SSC 234 increased linearly during ripening process when stored until 30 days at 13.5°C 235 (Fig.5). Additionally, SSC increased proportionally with the concentrations of $CaCl_2$ 236 (Fig. 5). The lowest SSC were observed in control (0% CaCl₂, 13.64°Brix) and in 237 opposite, 4% of CaCl₂ increased the SSC (13.31°Brix). These results suggest that, 238 hydrothermal (control) treatment delayed the conversion of the starch to sugars and 239 that the hydrothermal treatments associated to the higher concentrations of calcium 240 chloride had higher soluble solids contents; therefore they were in a more mature 241 maturation stage. The banana's SSC increased to a maximum of 27% in the ripening 242 process, with a small decrease when the fruit is very ripe/senescence stage 243 (Bleinroth, 1995). Remarkably, Coelho et al., (2001) showed that banana fruit cv. 244 'Prata' hydrothermal treatment at 50°C, 3' and 8' storage at room temperature (25°C) 245 increased SSC around 23 ~ 23.5 °Brix, receptivity.

246 There is no significantly difference in TA under CaCl₂ associated with 247 hydrothermal treatment. However, the ripening process affected significantly the TA 248 concentration over fruit storage (Fig.6). The acidity can be used as a point of 249 reference for fruit ripening, which is attributed mainly to organic acids. Organic acids 250 are used as a substrate during fruit respiration, leading ATP production in the 251 mitochondrial electron transport chain (mETC) Nunes-Nesi et al., (2013). Our results 252 showed an increased concentration during ripening process, which can be partially 253 explained by organic acid production by mainly TCA cycle pathway in the 254 mitochondria in comparison with degradation by respiration process. According with 255 Bleinroth (1995), banana fruit in green stage are characterized by low acidity which 256 can increase during fruit ripening reaching maximum values in senescence.

257 The pH variable showed a significate interaction (P < 0.05) between days after 258 storage and CaCl₂ concentration. During the storage time, the banana pulp pH was 259 reduced in all treatment (Fig. 7). Complementary, 30 days after storage all pH were 260 similar for all treatment with pH average 4.05, 4.05, 4.05, 4.04 and 4.04 in the 0, 1, 261 2, 3 and 4% CaCl₂ (w/v). Our results were in close agreement with previously 262 observed by Da Costa Gomes et al., (2007) in banana cv. 'Prata-Anã'. The reduction 263 in pH values over ripening is partially explained by increase in sugar contents with 264 decreasing in TA/SSC ratio (Braga et al., 2008).

265 The starch content was significantly affected by the ripening process as well by 266 CaCl₂ associated with hydrothermal treatment (Fig.8). As expected, the starch 267 content decreased during ripening process independently of the treatment (Fig. 8A). 268 Interestingly, each single day of storage, the starch content were decreased around 269 1.217% and the 1% of CaCl₂ treatment 0.5123%. After 30 days of storage, Control 270 (0% CaCl₂) showed starch content around 2% while, when treated with 4% CaCl₂, 271 the starch content was around 4.05%, indicating an efficient process to reduce 272 degradation of starch and reducing the starch conversion to sugars. The starch content increased under higher CaCl₂ concentrations, likely due to the lower 273 274 respiratory rate and higher stabilization of the pectin connections promoted by 275 calcium (Silva et al., 2015). According with Ali et al., (2004) the fruit softening occurs 276 due to deterioration of structural and non-structural carbohydrates such as, cell wall 277 and-or starch oxidation, resulting in an increase in the sugars content. In banana fruit 278 softening were reported by a coordinated degradation of pectic, hemicellulosic 279 polysaccharides in the cell wall and starch (Mbéquié et al 2009; Shiga et al., 2011). In 280 banana, several genes are involved in starch-to-sugars conversions during ripening 281 process, this has been reported, including the amylases such as MAmy, Ma-bms, Maisa and MaDEBs (Bierhals et a., 2004; Do Nascimento et al., 2006; Jurda et al., 282 283 2016 and Junior-Nascimento and Lajolo, 2006). During banana ripening, is one of the 284 most notable changes during the conversion of starch to simple sugars such as 285 glucose and fructose (8-10%) and sucrose (10-20%) (Viviani and Leal, 2007).

In order to better understand the role of hydrothermal treatment associated with CaCl₂ in sugar content, we evaluated the reducing, non-reducing and total sugar accumulated during fruit ripening (Fig.8B, C and D). The total sugar (Fig.8B) increased significantly during ripening process over storage time with a daily increase 290 of 0.998%. Interestingly, the highest total sugar levels observed were those when 291 treated with increasing CaCl₂. The sugar content determines the degree of 292 sweetness of the banana and together with the acidity, is a measure more directly 293 correlated with the taste quality (Wu et al., 2005). The reducing sugar and non-294 reducing sugar as total sugar were significantly affected by ripening process over 295 storage time as well as by CaCl₂ treatment (Fig.8 C and D). Both sugars has their 296 concentration increased during storage, with increase in 0.7738% and 0.204% to 297 reducing and non-reducing sugars respectively for each day of evaluation. According 298 with previously observed by (Jesus et al., 2004), 23.6% of reducing sugars and 1.3% 299 of non-reducing sugar.

300

301 2.11. The PME activity

302

303 To further understand the effect of chloride calcium on fruit firmness we have 304 measured the pectinmethylesterase on banana's fruit previously treated with 305 hydrothermal with subsequence different CaCl₂ concentration (Fig.9). The PME 306 activity started increasing sharply after hydrothermal and CaCl₂ treatment until 10 307 days after storage, reaching up to 2-fold in comparison with the initial value for all the 308 treatments (Fig.9). Surprisingly, no difference was observed in its activity 309 independently of CaCl₂ concentration (Fig.9). PME activity started decreasing 310 gradually after day and by day 20 was as low as on day 0. Therefore, in can suggest 311 that the treatment as preciously observed in fruit firmness does not provide a beneficial effect on cell wall degradation in banana fruit cv. 'Prata Gorutuba'. A 312 313 similar pattern was observed during banana ripening with increases followed by 314 decreasing on enzyme activity in banana pulp over ripening stage (Hultin and Levine, 315 1965). Differently as we observed in our study, a common answer is an inhibition on 316 PME activity under calcium application as previously showed in different fruits such 317 as in apples (Ortiz et al., 2011), sweet pepper (Capsicum annum L.) (Rao et al., 318 2011), According with Almeida and Huber (1999), changes in the cell wall-related 319 enzymes such as PME, during fruit ripening is dependent of pH apoplast-variation. 320 We suggest that with a few changes in banana pH as reported in Fig.7, the PME 321 activity has not affected by CaCl₂ after hydrothermal treatment.

323 CONCLUSION

- 324
- 325 The hydrothermal treatment presents a better post-harvest quality of the banana
- 326 'Prata Gorutuba' when associated with calcium chloride. The hydrothermal treatment
- 327 and immersion in calcium chloride maintained the skin green color of the fruits until
- 328 fifteen days of storage.
