

SOIL FERTILITY DELINEATION TECHNIQUES AND RICE PRODUCTION

ABSTRACT

Determination of soil fertility with minimum data set for crop zoning and devising fertilizer recommendations. Soil fertility evaluation method based on pH, cation exchange capacity (CEC), soil organic carbon (SOC), available phosphorus (P), sulphur (S), zinc (Zn), boron (B) and exchangeable potassium (K). The data were collected from existing literatures and scoring was done on 0–100 scale. The lowest score was assigned for the minimum value of tested attributes and then gradually higher scoring values. Arithmetic, weighted, geometric and most minimum of mean scores were calculated and their performances were compared with grain yield of dry season irrigated (Boro) rice. Soil fertility in 10-12 and 39-52 percent areas of the country are very low and low, respectively. Medium fertile and fertile soils are distributed in 17-41% and in about 8% areas of the country. About 55% soils scored 70–95 (medium to high SOC) and the rest belongs to inferior quality. In some areas P build up has taken place (25% areas), but widespread K mining. Sulphur and Zn status in about 40 areas are low to very low (scored <35 and <40). Soils of the major areas of the country are with low pH (5.0-6.0) and CEC in the range of 15-25 cmol_c kg⁻¹. Weighted mean score and most minimum of eight attributes score showed good relationships with dry season irrigated rice yields than other tested methods indicating that this technique can be used for soil fertility rating in tropical countries.

Key words: Soil attributes, Score, Weighted mean, Most minimum mean, Maps

26 **1. NTRODUCTION**

27 Global population is increasing and so does the demand for food production, which has
28 already created tremendous pressure on soil, a finite resource for mankind. It is our obligation
29 to keep soil healthy and productive through appropriate amendments and crop management
30 practices [1]. Indigenous nutrient supplying capacity and fertilizer management may make a
31 soil fertile for one type of crop but could be deficient for the others. So, determination of soil
32 fertility range would be important not only for producing healthy crops economically but also
33 for maintaining its productivity for future generations. Soils in Bangladesh are exposed to
34 high temperatures mostly; plenty of rainfall and greater pressure from growing two or more
35 crops in a year with or without balanced fertilizations [2] and thus nutrients mining are
36 widespread. New nutrient deficiencies are emerging [3], and there might be potential hidden
37 hunger for many others that need to be identified for efficient crop production.

38 Soil fertility varies among regions indicating that variable amounts of fertilizers need to be
39 applied for different types of crop production. Inadequate dose will impair crop yield, while
40 overdose can cause not only economic losses but also could be responsible for environmental
41 pollutions [4]. So, a broad knowledge on soil fertility can provide a better perception on
42 current nutrient status, distribution patterns and trends [5] that can be obtained through geo-
43 statistical and geospatial analyses [6,7]. Such analyses help in decision making processes for
44 precision agriculture and thus for improvement of crop productivity [8,9].

45
46 Soil fertility can be determined in different ways [10,11] by using soil pH, SOC, P, K,
47 exchangeable calcium (Ca), magnesium (Mg) and aluminium (Al), S, etc [12,13]. Mbogoni et
48 al [14] evaluated soil fertility by using average weighted data on SOC, soil pH, total N,
49 electrical conductivity, C/N ration, available P, exchangeable Ca, Mg and texture for rice
50 based system productivity improvement. Khaki et al [15] utilized square-root method as
51 parametric approach and Joint Fuzzy Membership functions to compute soil fertility index

52 (SFI). They found both the system suitable for soil fertility mapping and showed good
53 relations with rice yield. Desavathu et al [7] used soil pH, EC, N, P and for soil fertility
54 evaluation through inverse distance weightage interpolation. Thus it is found that researchers
55 had taken initiative for making soil fertility maps for specific locations or regions but a
56 simple method for a country is still lacking. Therefore, the objective of this study was to use
57 geo-referenced data on selected soil attributes for preparation of soil fertility maps using
58 average, weighted mean, geometric mean and most minimum value techniques for
59 Bangladesh and to establish their relationships with rice yields.

60

61 **2. MATERIALS AND METHODS**

62 Data on soil organic carbon (SOC), available phosphorus (P), sulphur (S), zinc (Zn), and
63 boron (B), cation exchange capacity (CEC), soil pH and exchangeable K were collected from
64 Bangladesh Agricultural Research Council website, Soil Resource Development Institute and
65 existing available literatures. Average Boro clean rice (dry season irrigated crop, hereafter as
66 Boro rice) yields from 2007 to 2013 were collected from different volumes of Bangladesh
67 Bureau of Statistics and its relationships were established with soil fertility scores. Although
68 crop yields vary depending on inherent soil fertility, some other factors like electrical
69 conductivity, water quality (such as salinity) and its availability, agronomic management
70 practices, other biotic and abiotic factors also greatly influences crop productivity.
71 Nonetheless, inclusion of all those factors that influence soil fertility is beyond the scope of
72 the present investigation.

73 **2.1. Scoring criteria and map preparation**

74 Soil nutrient status in Bangladesh has been classified as very low, low medium, optimum and
75 high based on different ranges (Table 1). This classification system was considered for
76 assigning scoring values (Table 2) against each selected soil attribute. The scoring scale, as

77 considered in the present investigation, was 0–100. Attribute-wise soil fertility ratings over
 78 different locations of Bangladesh were made by using MS-Excel Macros and IDRISI3.2.

79
 80 Soil fertility scores, as determined by arithmetic mean (AM), geometric mean (GM),
 81 weighted mean and (WM) and most minimum attribute (MAtrib_{score}) techniques, were used to
 82 find out their relationships with Boro rice yields (64 districts of Bangladesh from 2007 to
 83 2013) through regression analyses. Considering higher R² values, final soil fertility rating
 84 maps were prepared based on weighted mean scores (Equa. I) and scores of the most
 85 minimum of eight parameters for each district (Equa. II). Among soil attributes the most
 86 limiting factors dictate crop yield, so we have provided weight to such factors in determining
 87 WM as follows:

88
 89
$$WM = ([SOC_{score}] * [P_{score}] * [K_{score}] * [CEC_{score}] * [pH_{score}])^{(1/5)} * 0.5 + [S_{score}] * 0.25 +$$

 90
$$([Zn_{score}] * [B_{score}])^{(1/2)} * 0.25 \dots\dots\dots (I)$$

91
 92 where, SOC_{score} is the soil organic carbon, P_{score}, K_{score}, CEC_{score}, pH_{score}, S_{score}, Zn_{score} and
 93 B_{score} stand for phosphorus, potassium, cation exchange capacity, soil pH, sulphur, zinc and
 94 boron scores, respectively.

95 MAtrib_{score} for selected eight soil parameters were determined as follows:

96
$$MAtrib_{score} = Geomean(Small(Atrib1:Atrib8,1), Small(Atrib1:Atrib8,2), \dots, \dots, \dots,$$

 97
$$Small(Atrib1:Atrib8,8)) \dots\dots\dots (II)$$

98 where, Atrib1, 2, 3,, 8 are the soil parameters considered first, second, etc.

99
 100 GM score was calculated as follows:

101
$$GM = ([B_{score}] * [K_{score}] * [P_{score}] * [CEC_{score}] * [pH_{score}] * [SOC_{score}] * [S_{score}] * [Zn_{score}])^{(1/8)} \dots (III)$$

102
 103 AM score was computed as follows:

104 $AM = ([B_{score}] + [K_{score}] + [P_{score}] + [CEC_{score}] + [pH_{score}] + [SOC_{score}] + [S_{score}] + [Zn_{score}]) / 8 \dots\dots (IV)$

105

106 Scores for most minimum of 1, 2, 3, 4, 5, 6 and 7 soil attributes were also found out in similar
107 fashion of Equa. II. The maps of tested attributes were prepared by using IDRISI3.2. Soil
108 fertility rating maps on the basis of WM and most minimum of eight attributes were used for
109 soil fertility delineation in Bangladesh. The other maps prepared based on different
110 techniques were used as supplementary figures.

111 **3. RESULTS**

112 Soil organic carbon, a vital component of fertility index showed >95 score for about 25%
113 areas in Bangladesh (Fig. 1a). About 55% soils had 70–95 score (medium to high SOC) and
114 the rest belongs to inferior quality. The scores for soil P varied from <10 to >75 in which
115 very low (<7 ppm), low (7-15 ppm), optimum (15-30 ppm) and high (>30 ppm) P levels
116 covered about 22.64, 47.74, 12.98 and 16.64 percent areas in the country (Fig. 1b). About
117 25% soils are with optimum/high (>80 score) K fertility. Majority areas (~43%) bear low K
118 (0.091-0.18 meq 100 g⁻¹ soil) and the rest belong to very low (<10 score) and medium (40-80
119 score) K categories y (Fig. 2a). The least score (<10) for S indicated that about 15.62% soils
120 are very poor (<7.5 ppm); 26.04% low and 14.54% medium and 43.79% areas are with
121 optimum/high S fertility status (Fig. 2b). In about 37.61% areas (score >75), soil Zn contents
122 are optimum to high (>1.351 ppm), 20.77% areas (40-75 score) are with medium Zn
123 containing soils and 41.61% soils scored <10 to 40 indicating (Fig. 3a) that Zn application is
124 a must practice for Bangladesh. Boron fertility is very low to low in about 50% soils (score
125 <10 to 40) and rest of the soils had medium B content (Fig. 3b).

126

127 Soil pH score varied from <25 to >85 depending on locations and soil types in the country.
128 Maximum area coverage was 44.59% followed by 32.25% in the pH range of 5.0-6.0 and 6.5-
129 7.5, respectively (Fig. 4a). Soil pH below 5.0 and above 7.5 covers about 7.29% areas of the

130 country. The rest of the soils (15.22% areas) are with pH range of 6.0-6.5. The CEC scores
131 ranged from <25 to >85 depending on location in the country (Fig. 4b). The CEC of major
132 soils (47.46%) are 15-25 $\text{cmol}_c \text{ kg}^{-1}$ followed by less than 15 $\text{cmol}_c \text{ kg}^{-1}$ in 37.72% areas of
133 the country. Higher CEC (>25 $\text{cmol}_c \text{ kg}^{-1}$) was found in 14.81% areas only.

134

135

136 **3.1. Soil fertility relationships with rice yield**

137 Soil fertility score based on different techniques and their relationships with clean rice yields
138 are shown in Fig. 5. About 49% yield variabilities are explained by the WM and most
139 minimum of eight tested soil attributes score (MAttrib-8). The performances of AM and GM
140 techniques in explaining yield variabilities were the least compared to others. Most minimum
141 1-7 soil attributes score explained Boro rice yield variabilities by about 23-42 percent.

142

143 **3.2. Soil fertility status**

144 Soil fertility scores varied from <35 to >60 with WM score technique and it was <35 to >55 with the
145 MAttrib-8 (Fig. 6). In the lowest soil fertility score (<35), area coverages are 10-12% of the country
146 based on above stated two techniques. The largest areas (28-30%) fall within the score of 40-45 under
147 both the techniques. Areas covered by higher scores (>55) were only about 16% of the country. Soil
148 fertility scores of 35-40 represented 9.41% and 24.08% areas under WM and MAttrib-8 techniques,
149 respectively. Similarly, 45-50 and 50-55 scores under WM and MAttrib-8 represented about 20% and
150 11-16% areas, respectively of the country. Based on GM, AM and MAttrib-1 to MAttrib-7 soil
151 fertility score varied greatly and represented different areas of the country, but major areas showed
152 low fertility score (data not shown). There were variations in the highest and the lowest scores
153 because of method employed (Table 3). The standard deviations were ± 8.52 , ± 7.19 , 7.73 and ± 8.52
154 for GM, AM, WM and MAttrib-8 means score, respectively having corresponding co-efficient of
155 variations of 19.62%, 14.22%, 16.58% and 19.62%.

156

157 **4. DISCUSSION**

158 In about 29% areas of the country, the SOC was at medium category; although there are high
159 and very high SOC in certain areas, especially with peat soils. In general, SOC was higher in
160 low lying areas, the single cropped zones, which remain 5–6 months under water in a year.
161 This level of SOC specifically in about 18% areas of the country is still inadequate for
162 satisfactory crop production [16]. As population pressure is increasing, farmers are using
163 such lands to increase total production through cropping intensification resulting in depletion
164 of SOC along with other essential plant nutrients. The decrease rate of SOC is comparatively
165 faster with arable cropping over time [17] with or without addition of organic manures. So,
166 we have found lower SOC rating in intensely cropping zones of Bangladesh. Partial
167 productivity of applied fertilizers is also decreasing indicating that nutrients from organic
168 matter (OM) need to be added that has been observed in our experiments at BRRI. Most soils
169 showed good response when OM was incorporated either from poultry litter, cow dung,
170 vermicompost [18,19] or green manuring because SOC influences soil pH, buffering
171 capacity, nutrient supplies and soil biological activity [20].

172
173 Although available P in the category of very low and low cover a larger area (about 70%), in
174 some areas its build up has taken place (Fig. 1b) because of cropping patterns followed, soil
175 acidity, fertilizer management options and inherent characteristics of parent materials [16,21].
176 As a greater area suffers from available P, corrective measures have to be taken for profitable
177 production [22]. This scenario is also true for global perspective in which P is depleting by
178 $5.1 \text{ kg ha}^{-1} \text{ yr}^{-1}$ [23]. However, majority of the farmers in Bangladesh prefer to add N
179 fertilizer because of its immediate visible effects [2] and thus nutrient imbalance impose
180 negative impact on soil properties and crop production as a whole.

181
182 Potassium levels in major areas were very low to low (Fig. 2a) indicating that K mining was
183 taking place because of its substandard dose used by the farmers. Since farmers generally use

184 more N fertilizer and minimum K rate, the later is depleting rapidly in many areas of
185 Bangladesh [21, 22, 24]. In the global perspective, K is also depleting by 38.8 kg ha⁻¹ yr⁻¹
186 [23]; although its build up is not either uncommon in some areas because of excessive use
187 with certain crops [16]. Though S and Zn deficiencies are widespread in the country, its wet
188 and dry depositions are also taking place because of industrial development [25]; but S
189 fertilizer application still improves rice yields in many areas of the country. The scenario of B
190 fertility is not healthy because in some areas it has depleted severely over time [16]. Yields of
191 wheat, mustard and papaya reduce greatly in many parts of the country without B application.
192 The depletion of soil fertility in areas with high cropping intensities [26] indicated that
193 replenishment of removed nutrients were not taking place or it is beyond the capacity of the
194 soils to supply major nutrients for growing high yielding crop varieties. There are evidences
195 that Zn and B contents have been depleted severely from 1991 to 2012 in some selected areas
196 of Bangladesh and thus crop productivity is declining [16].

197
198 Lower soil pH covers quite larger areas in the north and north-east part and higher pH in the
199 southern part of the country where essential plant nutrients availability is a limiting factor for
200 satisfactory crop production without proper amendment. In some cases soil pH is increasing,
201 especially in northern part of the country and thus playing a negative role on nutrient
202 availability. It was reported that nutrient availability from applied fertilizers may be
203 unavailable by more than 33-75% if soil pH ranges from 4.5 to 5.5 [27]. Generally, major
204 nutrients are available for plants when soil pH varies from 6.5 to 7.5 [28]. Among others, soil
205 P and many micronutrients become unavailable when pH exceeds 7.5, but molybdenum
206 availability increases in alkaline pH. Moreover, CEC also depends on soil pH in a neutral soil
207 will have higher CEC than acidic soils [29]. Low CEC indicates light textured soils having
208 tendency of K and Mg deficiencies and faster decrease in soil pH [29, 30]. In such situations

209 frequent liming is needed for sandy type soils than clay category for profitable crop
210 cultivation.

211

212 We have seen good relationships ($R^2 = 0.49$) of WM and MAttrib-8 scores with rice yields,
213 which is similar to the findings of Vasu et al. [31]. In Bangladesh, no grouping of soils has
214 been made based on combine scores or combine effects of different soil attributes; but
215 component-wise soil fertility delineations are available [22,26, 32]. So, our efforts are to
216 group soil fertility status combining all tested attributes as score <35 (very low fertility), 35-
217 45 (low fertility), 45-55 (medium fertile) and >55 (fertile). Accordingly, 10-12 and 39-52
218 percent areas of the country represented very low and low soil fertility, respectively (Fig. 6).
219 Medium fertile and fertile soils are distributed in 17-41% and in about 8% areas of the
220 country. These findings clearly indicate that special cares are needed for efficient and
221 economic crop production in major areas of Bangladesh. However, crop yields not only
222 depend on soil fertility, but also on other factors like water availability, temperature, and so
223 on. Moreover, soil fertility scores alone cannot explain yield variability of a crop rather it can
224 provide an indication for fertilizer rate determination and crop zoning for profitable farming.

225

226 Population pressure is increasing in Bangladesh, while soil fertility is decreasing indicating
227 that we are manipulating our soils beyond its bearing capacity. In general, nutrient mining is
228 taking place in Bangladesh at about $100 \text{ kg ha}^{-1} \text{ yr}^{-1}$ [22, 33] also reported low to very low
229 soil fertility for most of the studied soils in Bangladesh. This scenario is also true in terms of
230 global scale where soil fertility problems are associated with human-induced nutrient
231 depletion [23]. Besides, soil nutrient availability is limiting in cultivated lands of tropical
232 countries because of low inherent soil fertility [34]. Calcium deficiencies are emerging in
233 some agro-ecological zones (AEZ-3 and 21) of Bangladesh [3] and there might be hidden
234 hunger for micronutrients and thus reducing soil fertility and ultimately crop yield, but not

235 considered in the present investigation because of unavailability of data for the whole
236 country. In time series analyses for nutrient depletion, it was found that the contents of
237 exchangeable K, Ca and Mg have declined in all physiographic units except Old Himalayan
238 Piedmont and Madhupur Tract after 27 years of crop cultivation [35]. In one of our study, it
239 was also found that soil nutrient ratios have been changed in many places of Bangladesh
240 because of over exploitation of inherent soil fertility and thus Ca:P and N:Zn were playing
241 significant negative role with wet season rice yields under unfavourable ecosystems of
242 Bangladesh [36]. Similarly P: K ratio was acting antagonistically in agricultural ecological
243 zone 3, 18 and 26 of Bangladesh. All these factors indicate that we have to know our soils
244 before its use for crop production. Determination of soil fertility status by combining
245 important but minimum attributes can help in this regard for profitable farming and to
246 recuperate soil fertility through crop and fertilizer management.

247
248

5. CONCLUSION

249 A simple method of soil fertility evaluation for a country with minimum data sets is very
250 much desirable for proper crop zoning and delineating agronomic management options for
251 satisfactory crop production. We have determined soil fertility scores using pH, CEC, SOC,
252 available P, S, Zn, B and exchangeable K and following geometric, arithmetic, weighted and
253 mean approaches along with most minimum of tested attributes score. Weighted mean and
254 most minimum of soil attribute scoring methods showed better relationships with dry season
255 irrigated rice yields in Bangladesh indicating that this technique can be employed for soil
256 fertility assessment and its subsequent use for crop zoning and for determination of fertilizer
257 rates in similar environments around the globe.
