

1 **EDAPHIC FACTORS AND FLOODING PERIODICITY DETERMINING**
2 **FOREST TYPES IN A TOPOGRAPHIC GRADIENT IN THE NORTHERN**
3 **BRAZILIAN AMAZONIA**

4
5
6 **Abstract**
7

8 The Brazilian Amazonia is a region covered by an extensive mosaic of tropical forests
9 conditioned by different topographical and hydro-edaphic features. Although studies
10 relating environmental determinants of structure and floristic composition are
11 systematically evolving in the region, there is no doubt that there are still information
12 gaps due to the lack of research in peripheric areas of the Amazonia. The seasonally
13 flooded areas of the state of Roraima situated on rio Branco-rio Negro basin, northern
14 Brazilian Amazonia, still are deprived of such information. In this way, this work had as
15 objective determine the physical and soil chemical attributes, and the flooding
16 periodicity that characterize different forest types dispersed in a topographic gradient
17 located in an area on the north of rio Branco-rio Negro basin. Soil samples (0-60 cm)
18 were collected along a 2.7 km transect (31.1-64.8 m a.s.l.) crossing three different forest
19 types: (i) mosaic between treed and forested shade-loving (La+Ld), (ii) area of
20 ecological tension between forested shade-loving and open ombrophilous forest (LO)
21 and (iii) open ombrophilous forest (Ab+As). The results indicated different soil classes
22 and flooding periodicity for each forest type observed: Entisols Fluvents (La+Ld, 3-4
23 months flooded), Entisols Quartzipsamments (LO, 1-2 months) and Yellow Ultisols
24 (Ab+As, no flooding). All analyzed soils were defined as nutrient-poor areas, especially
25 those located on low altitude, characterized for higher hydrological restrictions
26 (seasonal flooding) aggregating forest types of lower structural patterns (e.g. La+Ld).
27 Soils on low altitude were also characterized as those with the highest percentage of fine
28 sand and silt, while soil free of seasonal flooding (Yellow Ultisols) presented the
29 highest levels of clay and coarse sand, always associated with the ombrophilous forests
30 (higher structural patterns). These results improve our understanding of the
31 environmental factors conditioning different forest types in this peripheral region of
32 Amazonia, suggesting that ecosystems with higher hydro-edaphic restrictions are a
33 strong indicator of forest types with lower structural patterns.

34 Keywords: oligotrophic ecosystems, water table, ecotone, phytophysiology.
35

36 **INTRODUCTION**

37 The Amazon basin occupies ~40% of the surface of South America and about 60%
38 is inserted within the Brazilian territory (Carvalho & Domingues, 2016). Its
39 predominant covering is defined as dense and open ombrophilous forests (Veloso et al
40 1991, Fearnside, 2018), but throughout the Amazonian biome there are many different
41 forest types that may be distinguished by their floristic composition and structure due to
42 the large environmental heterogeneity (Fearnside & Ferraz, 1995; Nogueira et al.,
43 2015). In general, the factors modeling the different forest types are attributed mainly to

44 the climatic variations, hydro-edaphic conditions, topography, and anthropogenic
45 interferences, all interacting and acting at different spatial scales (Castilho et al., 2006;
46 Phillips et al., 2003; Laurance et al., 1999; Franco-Moraes et al., 2019). This
47 congregation of factors generates different structural and floristic shades with different
48 ecosystem values, but generally information on the weight of each one, in the local and
49 regional context, is little known due to the gigantism of the Amazonia, which makes
50 sampling in peripheral areas a difficult process (Philips et al, 1998; Fearnside. 2008).
51 However, this kind of information is the basis for improving our knowledge on
52 specialization of the various Amazonian phytophysionomies, with different structural
53 patterns and species diversity, directly influencing the estimates of biomass/carbon
54 stocks and fluxes in this region considered to be the largest and most important "natural
55 environment" mitigating the harmful effects of global climate change (ter Steege et al.
56 2016; Lewis et al., 2004; IPCC. 2006)

Comment [J1]: Chronological order

57 Although studies involving edaphic and hydrological factors in association with
58 topographic gradients related to the dynamics of ecosystems have evolved rapidly in the
59 Amazon (e.g. Silva et al., 2016; Tuomisto et al. 2003; Tuomisto et al 2014), there is still
60 a great lack of information due to huge regional gaps with rare scientific investigations.
61 In this context, ecotone forests (transition areas, contact zones or areas of ecological
62 tension) are ecoregions representing about 15% of the biome (Santos et al. 2007), but
63 still have a lack of knowledge about the processes of their formation and maintenance
64 (Santos et al., 2013). These ecoregions are characterized by mosaics of different forest
65 types condensed into distinct spatial scales that hamper their floristic and structural
66 characterization and, above all, biomass/carbon estimates (Nascimento et al., 2014;
67 Barni et al., 2016). This scarcity is mainly detected in the northern of the Brazilian
68 Amazonia, especially in the seasonally flooded areas of the rio Branco-rio Negro basin
69 located in the state of Roraima (Silva et al., 2016; Mendonça et al., 2013, Damasco et
70 al., 2013).

Comment [J2]: Chronological order

71 Recent works have demonstrated that the ecosystems which form the mosaic of
72 landscapes in this region present a direct integration between the plant cover and the
73 physical, chemical and biological attributes of the soil (Mendonça et al., 2017), due to
74 essential processes related to the biogeochemical cycles, water table outcrops,
75 accumulation and decomposition of organic matter (Cordeiro et al. 2016; Silva et al.,
76 2016). This is a strong indication that environmental conditions associated with

Comment [J3]: Chronological order

77 temporal flooding, sediment drag, and nutrient leaching may have high importance in
78 the formatting of different forest types in this peripheral region of the Amazonia (Junk
79 et al., 2015; Suwa et al. 2013; Luizão et al. 2007). In the same context, the physical and
80 chemical attributes of the soil, altitude, flooding periodicity, drainage and microclimate
81 also ca considered as important determinants in the formation of different natural
82 environments with specific structural patterns (Khorramdel et al, 2013; Scaranello et al.
83 2012)

Comment [J4]: Chronological order

Comment [J5]: ?

84 The objective of this study was to determine the flooding periodicity and the
85 physical and soil chemical attributes that characterize a topographic gradient established
86 between the Água Boa do Univini River and the Cumarú Mountain, a peripheral area of
87 the Rio Branco-Rio Negro basin. This region belongs to the Serra da Mocidade National
88 Park, a federal protected area located in the state of Roraima, northern Brazilian
89 Amazonia. This region is formed by a large mosaic of forest and non-forest ecosystems
90 without rare scientific investigations about the role of hydro-edaphic factors as
91 determinants of different phytophysiognomies formations. Our results aim to improve
92 the understanding of the environmental factors that determine different forest types in
93 this region of Amazonia, indicating the association between environments with
94 higher/lower hydro-edaphic restrictions and their respective forest structural pattern
95 taking into account horizontal (stem diameter) and vertical (total height) parameters.

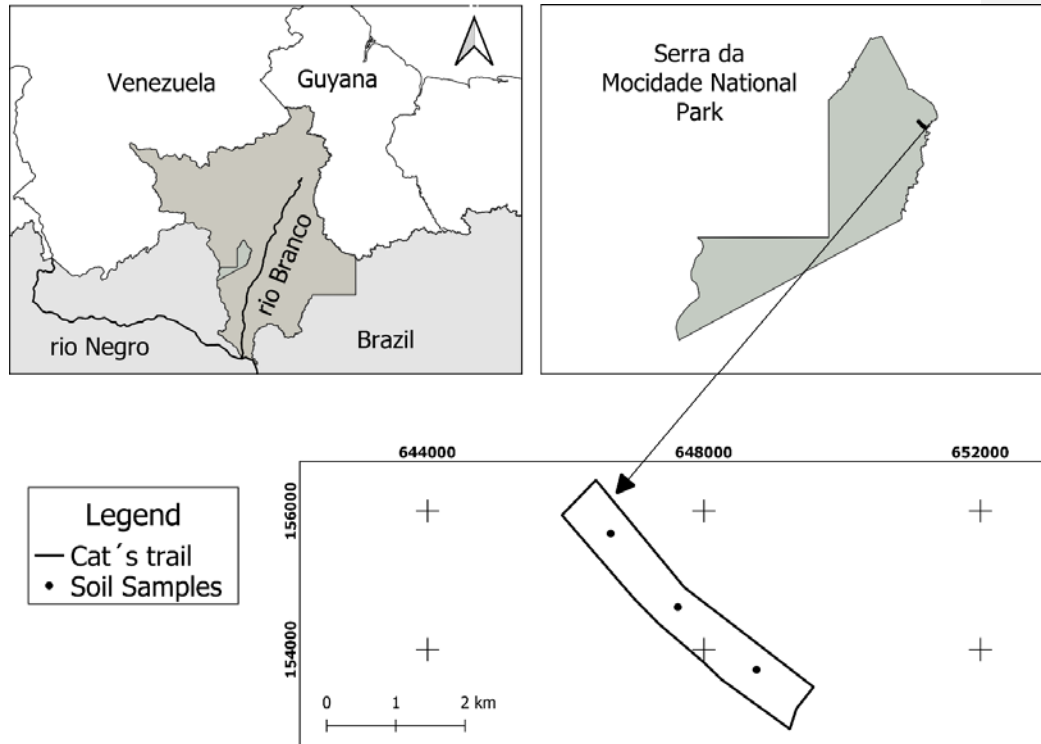

96 MATERIALS AND METHODS

97 Study area

98 This study was carried out in the Serra da Mocidade National Park (1.405° N -
99 61.648° W and 1.382° N - 61.673° W), a federal protected area managed by ICMBio
100 (Chico Mendes Institute for Biodiversity and Conservation), located in the municipality
101 of Caracaraí, ~ 290 km south of Boa Vista, capital of Roraima. The sampling area is
102 characterized by ecotone zones (area of ecological tension or transition area or contact
103 zone) between seasonally flooded forests under strong influence of the Água Nova do
104 Univini river (black water) in association with open ombrophilous forests that reach the
105 first steps of elevation of the Cumarú Mountain (Figure 1). The phytophysiological
106 characterization, edaphic and flood periodicity were performed in a topographic
107 gradient (31.1-64.8 m a.s.l.) inserted in an irregular transect (2.7 km long) known as
108 "Cat's Trail", which begins on the right bank of the Água Boa do Univini river to the

109 first steps of the northeast sector of the Cumaru Mountain, located at the northeastern
110 end of the National Park (Figure 1).

111 **Figure 1** - Study area indicating the geographical location of the Serra da Mocidade
112 National Park and the soil profiles sampled along the Cat's Trail.

113

114 **Characterization of the study area**

115 The National Park is totally inserted in the rainy tropical monsoon type (Am)
116 following Köppen classification, with annual rainfall of 1700-2000 mm and May-
117 August representing the rainiest period (~40% of annual rainfall) (Barbosa, 1997). This
118 region is marked by a chain of mountains that lends its name (Serra da Mocidade),
119 resulting from the erosion of the Guyanese Craton, a large continental block formed by
120 magmatic and metamorphic rocks dated between 1.8-2.5 billion years, in the Lower Pre-
121 Cambrian period (BRAZIL-MME, 1975). The characteristics of the main soil types in
122 the National Park region are defined from lithological residues of the same geological
123 constitution of the rock formation complex of the Serra da Mocidade, being a large
124 residual mass, with an altitude reaching ~1.800 m, characterized by sharp crests and
125 ravine slopes, covered by high altitude forests that lose this characteristic when reaching

Comment [J6]: Update reference. See Alvarez et al. 2014

126 the zones of flooded forests of low altitude and smaller biometric structural patterns.
127 Along this rocky complex, eight different soil classes can be found: Neossolo Flúvico
128 (Entisols Fluvents), Neossolo Quartzarênico (Entisols Quartzipsamments), Espodossolo
129 Humilúvico (Spodosols), Latossolo Amarelo (Yellow Oxisols), Gleissolo Háptico
130 (Entsols), Latossolo Vermelho (Red Oxisols), Neossolo Litólico (Entsols Lithic) and
131 Argissolo Amarelo (Yellow Ultisols) (BRAZIL-MME, 1975; USDA, 1999).

132 **Phyto-characterization and periodicity of flooding**

133 In order to carry out the phytophysionomic classification of the forest types in
134 the sample area, we adopted the criteria proposed by the Brazilian Vegetation
135 Classification System (BRAZIL-IBGE, 2012), based on a forest inventory
136 carried out along the entire transect at Cat's Trail (R. I.
137 Barbosa, personal communication). In this survey, the
138 structure (horizontal and vertical) and arboreal groups (trees
139 and palms) with stem diameter ≥ 10 cm were defined in each
140 forest type arranged along the topographic gradient (31.1–64, 8
141 m a.s.l.). The flood periodicity data were obtained from
142 observations performed in two consecutive rainy periods (2016
143 and 2017), where the sampling transect was coursed from start
144 to finish in both periods, estimating a mean time interval
145 (months) of flooding for each of them. All information was
146 aggregated into an ecosystem conceptual model that faithfully
147 followed the observed topographic gradient. Later, this model
148 was adopted as an associative basis of the chemical and soil
149 physical characteristics under each defined forest type.

Comment [J7]: Standardize text

150 **Soil sampling and physical/chemical analyzes**

151 In order to analyze and describe the physical and chemical attributes of the soil,
152 three profiles (1m wide, 1m long, 80cm deep) were opened for each forest type
153 considered. Soil samples were collected at 0-20cm, 20-40cm and 40-60cm depths. After
154 that, the samples were deposited in plastic bags and identified by forest type and depth.
155 All samples were air dried (TFSA), sieved (2 mm) and sent to the Soil Laboratory for

156 physical (% sand,% silt and% clay) and chemical (pH, organic matter, exchangeable
157 acidity, potential acidity, Ca, Mg, K, P, Cu, Zn, Fe, Mn and B) analysis following the
158 methodology specified by **EMBRAPA (2009)**. The descriptive classification of the soils
159 sampled was performed by the Brazilian Soil Classification System (**Santos et al., 2018**)
160 up to the third categorical level and correlated to the Soil Taxonomy (**USDA, 1999**).

161 **Ethical aspects?**

Comment [J8]: The licenses of ICMBio to enter in the National park should be presented.

163 RESULTS AND DISCUSSION

164 The three profiles open along the sampled transect of the Serra da Mocidade
165 National Park delimited three different types of soils: (i) Entisols Fluvents, (ii) Entisols
166 Quartzipsamments and (iii) Yellow Ultisols (Figure 2). All of them were characterized
167 as chemically poor (Table 1) and with high sand contents (Table 2). The results found in
168 the forest type classified as Treed and Forested shade-loving (La + Ld), 3-4 month
169 flooded in the year, are associated with the Entisols Fluvents, while Entisols
170 Quartzipsamments and Yellow Ultisols are associated, respectively, to the Area of
171 Ecological Tension (LO) and Open Ombrophyllous Forest (Ab+As) (Table 3). These
172 hydro-edaphic characteristics are similar to those reported in the Viruá National Park by
173 **Mendonça et al. (2013) and Damasco et al. (2013)**, a region with similar ecological
174 characteristics to the Serra da Mocidade, strongly indicating that soils with higher levels
175 of sand, low nutrient contents and higher flooding periodicity can define oligotrophic
176 forest types with lower structural patterns (vertical and horizontal), in counterpoint to
177 areas free of flooding processes, such as ombrophilous forests (Figure 3).

184

185 **Figure 3-** Conceptual model of the three forest types characterized by the soil classes
186 and flooding periodicity in a transect in the Serra da Mocidade National Park,
187 northern Brazilian Amazonia.

188 Entisols Fluvents can be considered as a low developed soil formed by
189 quaternary sediment deposits, where drainage varies from moderate to imperfect, and it
190 is very influenced by the outflow of the water table (Vale Jr. and Schaefer, 2010). In the
191 study area, this soil class was characterized by the predominance of high levels of fine
192 sand followed by the silt (Table 2), associated with mosaics of treed and forested shade-
193 loving, which are oligotrophic forest environments with low structural expression that
194 naturally dominate part of the rio Branc-rio Negro basin (Prance & Schubart, 1977;
195 Barbosa & Ferreira, 2004; Mendonça et al., 2014). The pH in this environment showed
196 a tendency to reduce as a function of soil depth, due to the high levels of fine sand,
197 which facilitates the processes of water percolation and nutrient leaching (Quesada et
198 al., 2009). The available phosphorus also presented a decrease with depth, being this a
199 process associated to alluvial sediment entrainment condition of the high parts of the
200 topographic gradient, considering that the parts of lower altitude are characterized by
201 more restrictive soils (3-4 months flooded) that may eventually accumulate higher
202 levels of fertility in the early layers in contrast with deeper layers (Suwa et al., 2013).

203 Our sampling in the profile of this soil class indicated that the organic matter had
204 the highest values in the first sampling layer (0-20 cm). This result is in agreement with
205 that presented by Ferraz et al (1998) and Luizão et al. (2007), where the authors suggest
206 that soils with higher elevations tend to have higher clay contents compared to lowland
207 soils, but the organic matter contents are higher in the first layers of lowland soils due to
208 the strong drag provided by the topography of terrain. Concerning to the physical

209 properties of this soil class situated in the La+Ld forest type, it was verified higher
210 concentrations of silt and fine sand, which are textural particles fully compatible with
211 natural lowland environment (Magalhães and Gomez, 2013).

212 Entisols Quartzipsamments is characterized as a soil under Area of Ecological
213 Tension (LO), 1-2 months flooded in the year, and it can be described as a soil class
214 extremely weathered, much quartzous, where almost all the clay is destroyed by
215 acidolysis, or sandy deposits formed by wind phenomena, occurring in flat reliefs or
216 basin reliefs or even in soft undulating reliefs (Vale Jr. & Schaefer, 2010; Santos et al.,
217 2018). This class of soil presented high levels of fine and coarse sand (Table 2), where
218 these physical characteristics are associated to the formation processes of this
219 environment, especially by the presence of small streams that precede the first
220 undulating steps of the Cumaru Mountain, with undulations which aid the accumulation
221 of alluvial material derived from the highest part. Thus, this soil type is related to the
222 hydrological processes of sediment trapping, as also observed by Mendonça et al.,
223 (2013) in the region of the National Park of Viruá (Roraima), in similar environments to
224 those found in Serra da Mocidade.

225 The pH values determined for this soil class in the study area are in line with the
226 standards reported by EMBRAPA (2009). An analysis along the soil profile in this
227 forest type allowed to understand that there is a slight increase in the pH values from the
228 most superficial layer (0-20cm) to the deepest ones (20-40cm, 40-60cm) and,
229 consequently, a reduction in exchangeable and potential acidity (Table 1). This is a
230 process fed by the infiltration of exchangeable bases or increase of organic matter, as
231 previously established by Santos et al. (2011). Likewise, the values of available
232 phosphorus presented a decrease between the second (20-40 cm) and the third layer (40-
233 60 cm), being a strong indicative of the reduction of this element along the vertical soil
234 profile, as observed by Duivenvoorden. (1996), and it can act as a limiting element in
235 the larger / smaller vertical and horizontal structuring of the forest.

236 Organic matter also declines from the superficial to the deeper layers of this soil
237 class in the study area. This same observation was reported in the Viruá National Park,
238 with the authors suggesting that the topography of the terrain, especially those with soft
239 ripples, may retain organic matter in the superficial layers of the soil due to the sediment
240 trapping or the temporal outcropping of the water table (Mendonça et al., 2013), which
241 are the same environmental characteristics observed in the ecotone (LO) of the Cat's

242 Trail. In the same sense of the organic matter, the CEC also has a reduction pattern from
243 the most superficial to the deepest layers, presenting a CEC saturation problem with the
244 exchangeable Al, being common in this soil type, which can be aggravated by depth due
245 to the decrease of organic matter in the soil and exchangeable bases such as Ca^{2+} , Mg^{2+}
246 and K^+ , which would limit the development of the roots of the plants and affect the
247 structure of the forest (Sacramento et al., 2008).

248 The Yellow Ultisols is characterized as a soil type flooding free, with strong
249 presence of Open Ombrophylous Forest (Ab+As), with high contents of coarse sand and
250 clay (Table 2). According to Vale Jr. and Schaefer (2010), the formation factors of this
251 soil class are similar to that of the Oxisols, with the same geomorphological
252 characteristics and natural vegetation, but with a textural gradient. The pH values found
253 in this environment are slightly acidic and there is not much difference between the
254 layers (Table 1). This process may be happening due to the absence of both water table
255 outcrops and temporal flooding in this area (Quesada et al., 2009; Scopel et al., 2005).
256 The content of organic matter found in this soil type was high in the first layer,
257 decreasing drastically towards the deeper layers. This result indicates a direct
258 relationship with the CEC values found in this soil type, within the relational
259 congruence suggested by Ostertag (2001), where organic matter and clays are the
260 edaphic parameters with the greatest contribution to the formation of CEC values.

261 In this same analytical path, the concentrations of the micronutrients observed in
262 the profile of this soil highlight the higher concentration of Fe in the first two layers (0-
263 20 cm and 20-40 cm), being this element the main constituent of the structure of the
264 clays (Tsui et al., 2004). This chemical characteristic was also observed in the
265 ombrophilous forests of the Viruá National Park by Mendonça et al. (2017), suggesting
266 that higher Fe contents in the ombrophilous forests of regions under the influence of
267 treed and forested shade-loving mosaics may be due to the high presence of mineral
268 particles (oxides of iron) derived from the organic matter deposited on the soil in litter
269 form. This indicates that both Fe and the other micronutrients (Zn, Mn, B, Cu) have an
270 important role in the nutrient cycling of this forest environment, but without a clearly
271 defined role as a characterizer of forest types. This evidence the large range of
272 uncertainties that still persist in the evaluations on the relationships between hydro-
273 edaphic conditions and their role in the construction of Amazonian ecosystems. In this
274 way, it is inferred that a better spatial distribution of the pedo-phytosociological studies,
275 addressing peripheral regional gaps, can help us to generate environmental standards

Comment [J10]: Chronological order

276 (topographic gradients, periodicity of flooding, soil classes) that more accurately
 277 configure the particular structural and floristic characteristics of different forest types,
 278 allowing better accuracy in biomass/carbon estimates, and giving the real importance of
 279 the Amazonia in the context of the global warming mitigation.

Where: Arg Clay (<0.002mm), Sil Silt (0.053-0.002mm), Total ArT_Area, ArG_ Thick Sand (2.00-0.210mm), ArF_ Fine Sand (0.210-0.053mm).

Table 3 - Soil classes, flood periodicity and structural parameters (DBH and total height) of the forest types observed in the sampling transect formed by the Cat's Trail, Serra da Mocidade National Park. Where: La + Ld = Mosaic of treed and forested shade-loving; LO = Area of ecological tension between forested shade-loving and ombrophylous forest; Ab + As = open ombrophylous forest associated with the first steps of the Cumaru Mountain. Different uppercase (Trees, ANOVA followed by Tukey test) and lowercase (Palms; Test t) letters in the columns indicate discrepancies ($\alpha = 0.05$) between the values of the taxonomic groups.

Forest Type	Density (ind ha ⁻¹)		DBH (cm)		Ht (m)	
	Trees	Palms	Trees	Palms	Trees	Palms
La+Ld	940	0	13.7± 3.3 A	-	12.2±2.3 A	-
LO	710	45	17.3± 7.4 B	14.5±3.5 a	17.7±2.7 B	17.5±1.9 a
Ab+As	423	85	20.9±12.9 C	18.5±6.5 b	18.3±4.0 B	16.6±3.2 a

(*) DBH = diameter at breast height (cm) and Ht = total height (m)

323

324 CONCLUSION

325 We conclude that each soil class determined in this study has a strong
326 association with the topographic gradient sampled in the study area situated on Serra da
327 Mocidade National Park, where lower altitude environments with larger flooding
328 periods are related to forest types of lower structural pattern (e.g. treed and forested
329 shade-loving) preferentially on oligotrophic soils (poor and sandy). These
330 characteristics indicate the formation of environments influenced by continuous hydro-
331 edaphic and geological processes, where seasonal flooding and sediment trawling are
332 part of the process of formation of the main forest types in the study area. Therefore,
333 edaphic factors and flooding periodicity are environmental characteristics that act as
334 environmental filters **wichic** are important in the formation of the landscape in this
335 region of rio Branco-rio Negro basin. These results improve our understanding of the
336 environmental factors that determine different forest types in this region of the
337 Amazonia, where environments with higher hydro-edaphic restrictions are a strong
338 indicator of forest types with lower vertical and horizontal structure.
